Introduction

Bone volume at the implant site is the local determining factor in deciding on the therapeutic placement of single or multiple dental implants. The implant is solely destined to replace the root structure of missing teeth and, as such, bone volume should be sufficient, as the implant usually occupies less volume than the original root. However, if edentulism is old and/or extends over two or three teeth, a clinical and radiological examination may reveal insufficient bone volume.

The odontological maintenance of alveolar bone volume is a peculiarity, since all skeletal bones except for dental alveolar bone demonstrate volume stability over time. The alveolar bone that supports teeth is a specific bone entity with a unique biologically labile structure in the absence of any loading. Therefore, the first biological question that arises is: how can this bone lability be explained and can it be prevented?

This fundamental problem is interesting for the implantologist, as implant placement depends on im-

- 1) What are the parameters and mechanisms that determine the volume of skeletal bone?
- 2) What are the biological and/or pathological mechanisms leading to anatomical bone changes and bone loss?
- 3) If bone loss occurs, which biological mechanisms are involved in the origin of bone repair?
- 4) If implant bone volume is insufficient, what is the biological pertinence of the different surgical procedures to restore it?

Parameters and mechanisms that determine skeletal bone volume

The volume of an object depends on its shape. This concept also applies in biology. Volume is thus determined by shape, which raises the question as to which parameters and mechanisms determine shape or, more precisely, the morphology of a skeletal bone.
